WARRANTY

This product is warranted to be free from defects in material and workmanship and, when properly used, will perform in accordance with specifications. Any GR-manufactured instrument, module, or part found not to meet this standard within a period of one year after original shipment will be repaired or replaced at no charge when returned to a GR service facility.

GR policy is to maintain repair capability for a period of ten years after the original shipment and to make this capability available at the then prevailing schedule of charges for any product returned to a GR service facility. Changes in the product not approved by GR shall void this warranty. GR is not liable for consequential damages.

This warranty is in lieu of all other warranties, expressed or implied, including, but not limited to, the implied warranties of merchantability and fitness for a particular purpose.
SPECIFICATIONS

**Frequency Range:** 5 Hz to 5 MHz.

**Output:** VOLTAGE: Max open-circuit output is at least 3 V for 20-kHz range, 2 V for 500-kHz range, and 1 V for 5-MHz range. IMPEDANCE: Source impedance for max output is approx 900 Ω. Output is taken from a 2500-Ω potentiometer. Source impedance for attenuated output is 200 Ω. One output terminal is grounded.

**Spectrum:** See spectrum-level curves and following table. Note: Spectrum level is shown with constant-Hz-bandwidth analysis, "white" noise being ideally flat. (Pink noise would slope down at 10 dB per decade.)

<table>

</tbody>
</table>

* Noise energy also beyond these limits. Level is down 3 dB at 5 Hz.

Waveform: Noise source has good normal, or Gaussian, distribution of amplitudes for ranges of the frequency spectrum that are narrow compared with the band selected. Over wide ranges the distribution is less symmetrical because of asymmetry introduced by the gas tube. Some clipping occurs on the 500-kHz and 5-MHz ranges.

Voltmeter: Rectifier-type averaging meter measures output. It is calibrated to read rms value of noise.

Attenuator: Multiplying factors of 1.0, 0.1, 0.01, 0.001, and 0.0001. Accurate to ±3% to 100 kHz, within ±10% to 5 MHz.

Available: Rack-adaptor set (19x7 in.); 1390-P2 PINK-NOISE FILTER.

Power: 105 to 125 or 210 to 250 V, 50 to 400 Hz, 50 W.

Mechanical: Convertible bench cabinet. DIMENSIONS (wxdh): Bench, 12.75x7.5x9.75 in. (324x191x248 mm). WEIGHT: 12 lb (5.5 kg) net, 16 lb (7.5 kg) shipping.

**1390-P2 Pink-Noise Filter**

**Frequency Response:** Sloping -3 dB per octave from 20 Hz to 20 kHz, -6 dB per octave above 20 kHz. Output voltage is approx -5 dB with respect to the input voltage at 20 Hz and -35 dB at 20 kHz. It lies within 1 dB of the straight line connecting these two points on a graph of output in decibels vs log frequency.

**Over-all Output Level:** When the filter is used with the random-noise generator set for the 20-kHz range, the output voltage of the filter is approx 30 dB below its input, and the voltage level in each one-third-octave band is approx 17 dB below that. Thus, when the output meter of the generator indicates 3 V, the output of the filter is approx 0.1 V, and the level in each one-third-octave band is approx 15 mV.

**Input Impedance:** The filter should be driven from a source whose impedance is 1 kΩ or less. Input impedance is variable from 6.5 kΩ + load resistance at zero frequency to 6.7 kΩ at high frequencies.

**Output Impedance:** The filter should not be operated into a load of less than 20 kΩ. Internal output impedance is variable from 6.5 kΩ + source resistance at low frequencies to approx 200 Ω at high frequencies.

**Max Input Voltage:** 15 V rms.

**Terminals:** Input terminals are recessed banana pins on ¾-in. spacing at rear of unit. Output terminals are jack-top binding posts with ¾-in. spacing.

**Mechanical:** Plug-in unit housing. DIMENSIONS (wxdh): 1.38x5x2.87 in. (35x127x73 mm). WEIGHT: 6 oz (0.2 kg) net, 4 lb (1.9 kg) shipping.

Section 1
INTRODUCTION

1.1 PURPOSE. The Type 1390-B Random-Noise Generator (Figure 1) provides a high level of electrical noise at its output terminals. This type of signal is useful in room acoustic measurements, loudspeaker and microphone tests, psychoacoustic tests, filter tests, crosstalk measurements for multichannel carrier systems, calibration checks on recording systems, modulation of signal generators and test oscillators, tests of rms response of meters, observation of resonance in systems, electrical averaging of resonant responses, and comparisons of effective band width. A pair of these generators can be used as signal sources for demonstration of various degrees of correlation, possible errors of random sampling, and other concepts of statistical theory.

1.2 DESCRIPTION.

1.2.1 CONNECTIONS. Two jack-top binding posts, used as output terminals, are provided on the panel of the Type 1390-B Random-Noise Generator.

1.2.2 CONTROLS. The following controls are on the panel of the Type 1390-B Random-Noise Generator:

Section 2

THEORY OF OPERATION

2.1 GENERAL. (See Figure 2.) The Type 1390-B Random-Noise Generator uses a gas-discharge tube as its noise source. A transverse magnetic field is applied to the tube to eliminate the oscillations usually associated with a gas discharge and to increase the noise level at high frequencies. The noise output from the gas tube is amplified in a two-stage amplifier. Between the first and second stages the noise spectrum is shaped in one of three different ways, depending on the setting of the RANGE switch. At the 20-kc position, a low-pass filter is inserted, which has a gradual roll-off above 30 kc, with the audio range to 20 kc uniform in spectrum level. At the 500-kc setting, a low-pass filter is inserted, which rolls off above 500 kc. At the 5-Mc setting, a peaking network is used. This network approximately compensates for the drop in noise output from the gas tube at high frequencies, so that a reasonably good spectrum is obtainable to 5 Mc.

2.2 OUTPUT VOLTAGE. The maximum open-circuit output voltage on the 20-kc band is at least 3 volts, on the 500-kc band at least 2 volts, and on the 5-Mc band at least 1 volt. This corresponds to a relatively high noise level, since the output impedance at maximum output is only about 900 ohms. This level can be expressed in terms of the resistance noise corresponding to 900 ohms at room temperature. The rms voltage in a one-cycle band due to thermal agitation in a 900-ohm resistor at room temperature is about 3.8 x 10^-9 volt. The level from the Type 1390-B Random-Noise Generator is about five millivolts for a one-cycle band when there is a total output voltage of one volt on the 20-kc band. This level, then, is about 1,300,000 times the corresponding voltage for resistance noise, or about 122 decibels above resistance noise at the same impedance level.

2.3 CHARACTERISTICS OF NOISE OUTPUT. As shown in Figure 3, no regular pattern appears in the output waveform; it is characterized by randomness rather than by regularity. Noise is therefore described by statistical means, and is characterized by its distribution of instantaneous amplitudes and by its frequency spectrum.

A random noise is often defined as a noise that has a "normal" or "Gaussian" distribution of amplitudes. This concept is illustrated by the following simple experiment performed with the noise generator.

Set the noise generator to the 20-kc band and to maximum output. Connect a small capacitor (about 1000 pf) across the output. Suddenly disconnect the capacitor. Measure its voltage with an electrometer or

---

---

Figure 2. Elementary Circuit Diagram.
its charge with a ballistic galvanometer. Record this value, which is the instantaneous amplitude of the noise voltage at the time the capacitor is disconnected. A series of these values can be obtained, and a graph prepared, with instantaneous amplitude versus the percentage of time during which any amplitude is exceeded. A large number of amplitudes must be determined in this way before a reliable distribution results. Two or three hundred observations are usually sufficient to show the trend for demonstration purposes, while several thousand will give a reliable curve for the important part of the range. Because of the large number of observations required, automatic apparatus is helpful in making these determinations.\(^3\)

Figure 4 illustrates a chart made up after 400 observations. This chart shows the fraction of observations in each interval of 0.2 volt. It is seen that most of the observations were relatively low values, although some relatively high values were observed. These results are also shown in a qualitative way in the oscillograms in Figure 3.

The normal (Gaussian or Laplacian) distribution curve is also shown in Figure 4. It has been adjusted according to the computed r.m.s. value of the data (the standard deviation) and the size of the interval used in plotting the data. The experimental data fit the normal curve very closely. Departures from the normal curve are almost entirely the result of so few observations. Had more observations been made, the result would have been even closer to the expected values.\(^3\)

In Figure 5, the probability that a voltage between two limits will be observed is given by the area under the normal curve between those two limits. Ex-
pressed in other terms, if the output voltage is observed over long periods of time, the fraction of the total time that the voltage is between the two voltage limits is given by the corresponding area under the probability curve. For example, the instantaneous voltage magnitude will be no more than one-tenth the r-m-s value for about eight percent of the time, and will be greater than three times the r-m-s value only about 0.26 percent of the time.

2.4 DEPARTURES OF OUTPUT FROM TRUE RANDOMNESS. The curve in Figure 5 is a theoretical curve and is symmetrical about the origin. The noise of the generator has a similar distribution, but is somewhat asymmetrical because of the gas tube. In addition, the inherent amplitude limitations of the vacuum-tube amplifiers limit the distribution curve at high levels. Clipping is most serious on the 500-kc and 5-Mc ranges. When a narrow-band filter is used at the output, the distribution becomes more nearly random.

2.5 FREQUENCY SPECTRUM OF NOISE. The meaning of the term "frequency spectrum of noise" is illustrated in the following experiment. If a wave analyzer, such as the Type 1900-A, set to a 50-cps bandwidth, is used to analyze the output of the noise generator, a fluctuating meter reading will be observed at any setting of the analyzer. If an average value of this reading is taken over a period of time, this average value is an estimate of the level in that 50-cycle-wide band. This level, determined on any range of the noise generator, is essentially independent of the frequency setting of the Type 1900-A Wave Analyzer. Thus the spectrum in this region is uniform. The relative spectrum on the noise can be determined by the use of suitable analyzers to cover the full range of the principal energy regions of the noise. A typical result of such an analysis is shown in Figure 6 for the three bands of the Type 1390-B Random Noise Generator. When the spectrum is uniform over a broad band, as shown in Figure 6, it is commonly called "white noise". The "whiteness" always applies to a definite band only. For example, if the noise spectrum is uniform from 100 to 500 kc, the noise is referred to as white in that band.

It is customary to adjust the measured value of analyzed noise to that corresponding to an ideal filter of one-cycle band width. Since noise voltage increases as the square root of the band width, the value determined on the Type 1900-A Wave Analyzer is then divided by \( \frac{\sqrt{50 \text{ cycles}}}{1 \text{ cycle}} \) to obtain what is called "spectral voltage density". This can be defined as the

\[ \text{Spectral Voltage Density} = \frac{\text{Measured Noise Value}}{\sqrt{50 \text{ cycles}} \over 1 \text{ cycle}} \]

2.6 ANALYSIS OF NOISE BY CONSTANT-PERCENTAGE ANALYZERS. If the output of the Type 1390-B Random-Noise Generator is analyzed by a Type 1564-A Sound and Vibration Analyzer, the results will be similar to those shown in Figure 7. Here the indicated level increases 10 decibels for each decade increase in frequency. This result can be understood by realizing that this analyzer has a bandwidth that is essentially a constant percentage of the center frequency. For example, at 5 kc the effective band width for noise is about 160 cps, and at 500 cps is about 16 cps.

2.7 TYPE 1390-P2 PINK-NOISE FILTER.
2.7.1 DESCRIPTION. The Type 1390-P2 Pink-Noise Filter (Figure 8) converts the electrical noise output

---

of the Type 1390-B Random-Noise Generator to "pink noise" (constant energy per octave) which facilitates measurements with constant-percentage-bandwidth analyzers. It is designed to plug into the output binding posts of the Type 1390-B Random-Noise Generator, but can also be used at any point in a system where this filter characteristic is needed. The filter is an RC low-pass filter with a slope of -3 dB per octave from 20 cycles to 20 kc and a slope of -6 dB at higher frequencies (See Figure 9). For shielding, the case of the filter is grounded to the LO input and output terminals. Figure 10 is a schematic diagram of the filter. The input terminals of the Type 1390-P2 Filter are recessed plugs at the rear and the output terminals are binding posts on the front.

Figure 8. Type 1390-P2 Pink-Noise Filter.

2.7.2 USE WITH THE TYPE 1390-B RANDOM-NOISE GENERATOR. Plug the Type 1390-P2 Pink-Noise Filter into the output terminals of the Type 1390-B Random-Noise Generator. The impedance of the load connected to the output terminals of the filter should not be less than 20 kilohms.

On the Random-Noise Generator, set the RANGE switch to 20 kc, the LOW-HIGH switch to HIGH, and the MULTIPLY BY switch to 1.0. The output of the Pink-Noise Filter will be approximately 30 dB below its input and the level in each one-third-octave band will be approximately 17 dB below that. Thus, when the output meter of the Random-Noise Generator indicates 3 volts, the output of the filter will be approximately 0.1 volt and the level in each one-third-octave band will be approximately 15 millivolts.

2.7.3 USE IN OTHER APPLICATIONS. When the Type 1390-P2 Pink-Noise Filter is used in a system at some point other than the output terminals of the Random-Noise Generator, the input source to the filter should have an impedance of less than 1 kilohm. Input connections can be made with clip leads or Type 274-MB Double Plugs to the recessed input terminals. The impedance of the load connected to the output terminals should not be less than 20 kilohms.

2.7.4 FREQUENCY-RESPONSE MEASUREMENTS. In many acoustical systems, frequency response measurements made with a sine-wave tone source are difficult to interpret because of the large amplitude fluctuations that may occur. When the measurements are made by effectively averaging the data over a narrow range of frequencies, response curve is considerably smoother and much easier to use. In the past, "warble tones" have been used for this purpose. A more convenient method, however, is to use pink-noise as the tone source and a constant-percentage-bandwidth analyzer (such as the Type 1564-A Sound and Vibration Analyzer) with one-third octave bandwidth as the frequency-determining element in the receiving system. The results of these frequency-response measurements can be conveniently recorded on the Type 1521 Graphic Level Recorder.

2.7.5 USE AS A NOISE SIMULATOR. Some noises that occur in nature are closer in spectral characteristics to pink noise than to white noise. This is true, for instance, of the low-frequency noise in semiconductors and of some acoustical background noises. To simulate electrical signals generated in such cases, it is convenient to use pink noise.

Figure 9. Typical frequency response of the Type 1390-P2 Pink-Noise Filter.

Figure 10. Schematic diagram of the Pink-Noise Filter.

Section 3
INSTALLATION

3.1 BENCH MOUNTING. To set the instrument in a tilted position (shown in inset of Figure 1), simply pull each front leg down as far as possible and then turn the leg so that its notch faces the back of the instrument.

To restore the leg to its retracted position, turn it to release the catch and push the leg up.

3.2 RELAY-RACK MOUNTING. Type 480-P412 Panel Extensions are available to adapt the Type 1390-B Random-Noise Generator for relay-rack mounting. To mount the Type 1390-B Random-Noise Generator in a relay rack, first attach the two panel extensions to the instrument. Remove the two screws in the upper and lower corners on one side of the panel. These screws fasten the panel to the aluminum end frames. Place one of the extensions in the front of the panel so that the corner holes on the plate line up with those on the instrument and replace the two screws.

Attach the second extension on the other side of the instrument panel in the same manner. The instrument can then be mounted in a standard 19-inch relay rack.

3.3 CONNECTION TO POWER SUPPLY. Connect the Type 1390-B to a source of power as indicated by the legend at the input socket at the rear of the instrument, using the power cord provided. While instruments are normally supplied for 115-volt operation, the power transformer can be reconnected for 230-volt service (see schematic diagram, Figure 12). When changing connections, be sure to replace line fuses with those of current rating for the new input voltage (refer to Parts List). Appropriate measures should be taken so that the legend indicates the new input voltage. On instruments changed from 230 to 115 volts, this simply means removal of the 230-v nameplate; a 115-v legend is marked beneath. For instruments changed to 230 volts, a nameplate (Type 5590-1664) may be ordered from General Radio.

Section 4
OPERATING PROCEDURE

4.1 START-UP. Turn the POWER switch on. After 30 seconds, when the heater of the Type 6D4 thyatron tube has warmed up, plate voltage is applied by an internal time-delay relay. (Simultaneous application of heater and plate voltage would shorten the useful life of the thyatron tube and increase the drift in noise-output level on warm-up.)

4.2 FREQUENCY CONTROL. The RANGE switch selects the network used for shaping the noise spectrum. Markings indicate the upper frequency limits for which the noise spectrum is reasonably uniform.

4.3 OUTPUT CONTROL. Output controls are a switch for selecting LOW or HIGH output, an OUTPUT level control, and an output attenuator. In the LOW position, the switch introduces a 10:1 resistance pad after the gas-tube noise source. This reduces the effect of the unavoidable amplitude limitations of the vacuum-tube amplifier and also reduces the noise field radiated externally by the instrument. To keep hum and microphonics to a minimum, however, it is generally advisable to operate the instrument in the HIGH position.

The OUTPUT level control is a continuous-type control that is used to vary the output voltage from a very low value to maximum for either setting of the output switch.

The MULTIPLY BY switch is used to provide low output levels. It has multiplying factors of 1.0, 0.1, 0.01, 0.001, and 0.0001.

4.4 VOLTOMETER. A rectifier-type, averaging meter measures the output voltage. It is calibrated to indicate the rms value of the noise. When the MULTIPLY BY switch is at 1.0, the meter indicates directly the open-circuit voltage at the output terminals. In the other positions of the MULTIPLY BY switch, the open-
circuit output voltage is the product of the meter reading and the multiplier reading.

The spectral voltage density of the noise at a given frequency is the r.m.s. voltage corresponding to the energy contained within a band 1-cps wide centered on that frequency. The typical spectral voltage density at 1 kc with one volt output is approximately as follows:

(a) 20-kc band: 5 millivolts for one-cycle band.
(b) 500-kc band: 1.2 millivolts for one-cycle band.
(c) 5-Mc band: 0.6 millivolt for one-cycle band.

When an accurate value is desired at any frequency, it should be measured. The values given are intended only as a guide.

4.5 LOAD. The output is taken from a 2500-ohm potentiometer, and one output terminal is grounded. For a truly resistive load with the MULTIPLY BY switch at 1.0, the apparent source impedance is zero when a reading of the voltmeter is taken with the load connected, since the voltmeter reads the voltage across the load. As the output control is varied from the maximum to the minimum setting, the actual source impedance varies from about 900 ohms to nearly zero. When the MULTIPLY BY switch is in any position other than 1.0, the source impedance is 200 ohms.

A load that is not independent of frequency will affect the frequency spectrum of the output noise. For example, a capacitor shunted across the output terminals will decrease the level of the high-frequency noise more than it decreases the level of the noise at low frequencies. The voltmeter is then less indicative of the spectrum level than it is for a resistive load.

4.6 HUM. The hum level is usually more than 40 db below the over-all noise level in the HIGH output position. This hum level is sufficiently low so that for most applications there is no effect from hum, even when an analyzer with a narrow band is used for analysis. The relative hum level in the HIGH output position is lower than that in the LOW position.

4.7 APPLICATIONS.
4.7.1 GENERAL. Some applications of a noise generator depend on its amplitude distribution characteristics (Figures 4 and 5). For example, the amplitude distribution is similar to that of speech, music, and many other sounds or electrical disturbances that occur naturally, while the amplitude distribution of a sine

---

---

of America (for which there are two comprehensive indexes available) and in various psychological journals. A useful bibliography for these applications is S. S. Stevens, J. G. S. Loring, and Dorothy Cohen, Bibliography on Hearing, Harvard University Press, Cambridge, 1955, particularly those references listed in Sections 139 (p. 571), 157 (p. 573) and 222-228 (pp. 579 f).

Other applications depend on the various possible frequency spectra of noise. The frequency spectrum is independent of the amplitude distribution, in the sense that a normal distribution of amplitudes is possible with any frequency spectrum - flat, broad, narrow, sloping, or peaked. Systems that affect one characteristic, however, may also affect the other. For example, nonlinear clipping affects both the amplitude distribution and the frequency spectrum. Linear filter networks used on purely random noise do not affect the randomness but alter the frequency characteristic and correspondingly the time scale. Linear filter networks used after clipped noise alter the frequency spectrum and also tend to make the noise more nearly random.

4.7.2 ELECTROACOUSTIC TESTS. The Type 1390-B Random-Noise Generator is a useful signal source for many types of electroacoustic tests, including loudspeaker-response tests. Some useful discussions of these tests using a noise source are given in the following: Leo L. Beranek, Acoustic Measurements, New York, John Wiley and Sons, 1949, pp. 639-640, 665f, 697-702; and RMA Standard SE-103, Speakers for Sound Equipment, April 1949, p. 6, Standard Test Signal BA.

Other General Radio instruments useful in electroacoustic tests are the Type 1551 Sound-Level Meter, the Type 1551-P1 Condenser Microphone System, the Type 1558 Octave-Band Noise Analyzer, the Type 1564-A Sound and Vibration Analyzer, and the Type 1521 Graphic Level Recorder.

4.7.3 ROOM ACOUSTICS TESTS. The noise generator is a useful signal source for many types of tests in room acoustics. These include reverberation tests, panel (wall and floor) transmission measurements, measurement of space irregularities, and measurement of steady-state signal transmission. For details, consult the following: Leo L. Beranek, Acoustic Measurements, New York, John Wiley and Sons, 1949, pp. 804 ff, 826 f, 831 and 883.

The Type 1551-C Sound-Level Meter, the Types 1550-A and 1558-A Octave-Band Analyzers, the Type 1564-A Sound and Vibration Analyzer, and the Type 1521 Graphic Level Recorder are useful elements in the over-all set-up for these tests.

4.7.4 STATISTICAL DEMONSTRATIONS. The properties of noise that concern the amplitude-time relationship are usually described by statistical means\(^2\). (Refer to paragraph 2.3.)

Random-noise generators can be used to demonstrate some concepts of statistical theory. The equipment and methods for demonstrating various degrees of correlation and possible errors of random sampling are described by J. C. R. Licklider and E. Dzendolet, "Oscillographic Scatterplots Illustrating Various Degrees of Correlation", Science, January 30, 1948, Vol. 107, No. 2770, pp. 121-124.

4.7.5 NOISE AT HIGH FREQUENCIES. The noise generator can be used to modulate an rf carrier when a noise signal is desired at a frequency above 5 Mc. A crystal diode modulator\(^8\) is a suitable instrument for wide-band modulation, and the Type 1363 VHF Unit Oscillators\(^9\) and the Type 1362 UHF Unit Oscillators are suitable rf oscillators covering the range from 65 to 920 Mc.

Because of the two sidebands that result from the standard modulation techniques, the noise band can be made to extend over a 10-Mc range, 5 Mc on each side of the carrier. For some applications it may be desirable to use a suppressed-carrier or balanced-type modulator (see Terman, Radio Engineering Handbook, New York, McGraw-Hill Book Co., 1943, pp. 551-553). It is also possible to use a series of carriers and modulators to combine to give a much broader band of noise than 10 Mc.

Some signal generators and oscillators include modulating circuits, so that an external source such as the Type 1390-B Random-Noise Generator can be used to modulate the signal. Instruments of this type are the Types 1003 and 1026 Standard Signal Generators. For these generators the modulation produced is limited to the audio range and to about 5 to 10 percent rms noise modulation, with peaks much higher. When a wider frequency band is desired, an external modulator should be used as described above.

---

4.7.6 VERY HIGH NOISE LEVELS. When noise levels even higher than those provided by the Type 1390-B Random-Noise Generator are desired, an amplifier should be used.

4.7.7 INTERFERENCE TESTS. Since noise is a common form of interfering or disturbing signal or signal that limits the threshold of detectability, the noise generator can be used to check receivers, communication systems, and detection systems for susceptibility to interference. It can also be used as a training aid for operators who must communicate through interference.

4.7.8 OVER-ALL CALIBRATION TESTS. The noise generator can be used as an over-all calibration device because of the wide frequency range available at the output. This calibration signal can be particularly useful in audio systems that involve a recording technique, and its use can frequently simplify the calibration procedure when an analyzer forms part of the system.\(^\text{10}\)

For example, when a magnetic tape recorder is used to record a signal to be measured on playback, reference signals must be recorded before and after the unknown signal is recorded. These reference signals permit one to fix levels and to determine response characteristics, which can vary from time to time depending on the condition of the tape and the machine. These reference signals are usually a series of tones at various points in the frequency range of interest. The noise generator, due to the broad frequency band, permits the use of a more versatile reference signal. Thus a useful set of reference signals would be a burst of noise of about one-half minute duration and a burst of a 400-cycle tone of about the same length. These two signals would permit the determination of frequency response, signal-to-noise ratio, harmonic distortion (at one level and one frequency), and flutter.

To determine the frequency response by use of a noise signal, perform the following operations:

1. Set the noise generator to the 20-kc range. Connect it to the input of the system under test, at such a level that the r.m.s input is at least 14 decibels below the sine-wave overload point.

2. Make a frequency spectrum analysis of the input noise signal and of the output noise signal from the device under test. The relative level of input and output as a function of frequency is then the frequency response of the device under test, unless spurious signals are present in the output of the device.

3. Test for spurious signals by making an analysis of the output with no input signal applied.

When these measurements are made, the input and output must be analyzed by analyzers of the same effective bandwidth. The bandwidth of the analyzer should also be appreciably smaller than the bandwidth of the device under test. Furthermore, the ultimate attenuation of the analyzer should be much greater than variation in response that one expects to measure, so that it will not limit the observed response. Distortion and background noise in the device under test will also limit the range of variation in response that can be measured by this method, and it is therefore important to select the proper level for input signal.

4.7.9 ANALYSIS OF NOISE. In the course of measurements with a noise generator, it is often necessary to make a frequency spectrum analysis of noise. The Type 1900-A Wave Analyzer, the Types 1558-A and 1558-AP Octave-Band Noise Analyzers, and the Type 1564-A Sound and Vibration Analyzer are useful accessories for this analysis in the audio-frequency range. The results of noise analyses by these different analyzers cannot be compared directly; the results must be modified because of the different bandwidths. Refer to paragraph 2.5 for a discussion of the frequency spectrum of noise.

---

---

The bandwidths of the Octave-Band Noise Analyzers increase in cycles directly with the mean frequency of the band. For that reason, a noise signal that is uniform in spectral-energy density over the frequency range will give higher-level readings for the higher-frequency bands than for the lower-frequency bands. The following table shows the values to be subtracted from the readings of the analyzer to obtain the spectral-density levels.
The effective bandwidth of the Type 1564-A Sound and Vibration Analyzer increases with increase in the frequency to which the analyzer is tuned. The graph in Figure 12 shows the value in decibels that must be subtracted from the reading of the analyzer to obtain the spectral-density level. This value is determined on the basis of initial calibration of the instrument by a sine-wave signal.

The corrections for spectral density level for the Type 1900-A Wave Analyzer are independent of the center frequency to which it is tuned but do depend on the bandwidth used. For the 3-cycle bandwidth subtract 3.7 db; 10-cycle, subtract 9 db; 50-cycle, subtract 15.9 db to obtain the spectral density level. (These correction numbers take into account the metering characteristic as well as the bandwidth.)

4.7.10 FREQUENCY RESPONSE MEASUREMENT. The noise generator can be used in place of the usual sine-wave generator for measuring the response of circuits and systems. In this application the selective characteristics of generator and detector are reversed from those ordinarily used in point-by-point measurements; the wide-band noise source and a selective detector replace the single-frequency source and wide-band detector. For speech and music circuits, this technique provides a much closer approximation to operating conditions than does the older system. This approach is particularly useful in testing recording systems.10 (Refer to paragraph 4.7.8.) The usual sweeping sinusoidal tests are sometimes inconvenient because of the problem of determining the recorded frequency during playback. This problem is eliminated by a recorded noise signal that is analyzed on playback.

Because of its broad frequency spectrum, noise is often used to avoid the marked resonant effects that can occur when vibrations in mechanical structures and acoustical systems are measured. The use of noise as a source in measuring the reverberation characteristics of rooms and the transmission characteristics of building structures results in a type of electrical averaging of the characteristics, provided a reasonably broad band is used. This averaging often simplifies the comparison of the characteristics of different structures.

The noise generator is useful in response measurements on loudspeaker systems in rooms.11 The electrically averaged response can be used to determine the optimum characteristic for equalizing networks, to set the relative levels of woofer and tweeter units, and to adjust levels of multiple-speaker units installed in different locations in a large hall.

4.7.11 RESONANCE TESTS. Because of its broad frequency spectrum, noise can sometimes simplify the search for resonant conditions in a system.12 The resonance produces a peak in the frequency spectrum, which can be observed in oscillographic displays.

4.7.12 OTHER USES. The noise generator can also be used in crosstalk measurements13, for masking crosstalk in multichannel communication systems14, to drive vibrators in component testing15, for noise factor comparison tests16, or distortion measurements17.

5.1 SERVICE. The product warranty stated above attests the quality of materials and workmanship in our products. When difficulties do occur, our service engineers will assist in any way possible. If the difficulty cannot be eliminated by use of the following service instructions, please write or phone our Service Department (see rear cover), giving full information of the trouble and of steps taken to remedy it. Be sure to mention the serial and type numbers of the instrument.

Before returning an instrument to General Radio for service, please write to our Service Department or nearest Sales Engineering Office, requesting a "Returned Material Tag." Use of this tag will ensure proper handling and identification. For instruments not covered by the warranty, a purchase order should be forwarded to avoid unnecessary delay.

5.2 MINIMUM-PERFORMANCE STANDARDS.

5.2.1 Equipment Required.

A true-rms ac voltmeter, such as the Hewlett-Packard Model 3400 or equivalent, is required for the following minimum-performance tests. (A 776-A BNC-to 274 Patch Cord can be used to connect the Model 3400 Voltmeter to the 1390-B.)

5.2.2 OPEN-CIRCUIT OUTPUT-VOLTAGE TEST.

a. Connect the rms voltmeter to the OUTPUT terminals of the 1390-B.

b. Set the 1390-B as follows:

   RANGE ------ 20 kHz
   MULTIPLY BY ------ 1.0
   LOW-HIGH ------ HIGH
   OUTPUT ------ Fully clockwise
   POWER ------ ON

c. Both the rms voltmeter and the panel voltmeter on the 1390-B should read 3.0 V or higher.

d. Change the RANGE switch to 500 kHz. The voltmeters should now read 2.0 V or higher.

e. Set the RANGE switch to 5 MHz. The voltmeters should now read 1.0 V or higher.

5.2.3 OUTPUT ATTENUATOR CHECK, 20 kHz.

a. Set the 1390-B as follows:

   RANGE ------ 20 kHz
   MULTIPLY BY ------ 1.0
   LOW-HIGH ------ HIGH

b. Connect the rms voltmeter to the OUTPUT terminals of the 1390-B and set the OUTPUT control to give a reading of 3.0 V on the 1390-B meter. Note the reading of the rms voltmeter.

c. Set the MULTIPLY BY switch to 0.1 and reset the OUTPUT control for 3.0 V on the 1390-B meter. The rms voltmeter should now read 1/10, ±5% of the previous reading.

d. Repeat this check with the MULTIPLY BY switch at .01, .001, and .0001. The rms voltmeter readings should drop by a factor of 10, ±5% for each step.

5.2.4 OUTPUT ATTENUATOR CHECK, 5 MHz.

a. Set the 1390-B as follows:

   RANGE ------ 5 MHz
   MULTIPLY BY ------ 1.0
   LOW-HIGH ------ HIGH

b. Set the OUTPUT control for a reading of 1.0 V on the 1390-B meter. Follow the procedure of para. 5.2.3 except allow a ±10% tolerance for each step.

5.2.5 HIGH-LOW CHECK.

a. Set the 1390-B as follows:

   RANGE ------ 20 kHz
   MULTIPLY BY ------ 1.0
   LOW-HIGH ------ HIGH

b. With the rms voltmeter connected to the OUTPUT terminals on the 1390-B, set the OUTPUT control for a reading of 3.0 V on the rms voltmeter.

c. Change the HIGH-LOW switch to LOW. The rms voltmeter should now read between 0.3 and 0.6 V.

5.3 ACCESS TO COMPONENTS. To remove the shield, loosen the two fluted locking screws on the back of the instrument. These will unlock on the first turn, but should be loosened the maximum amount before the shield is removed. Pull the shield straight back from the panel.

5.4 PRELIMINARY CHECKS. If the noise generator is inoperative, make the following checks before removing the case. Make sure that the ac supply is plugged into a live power line, that the power switch is turned to the POWER position, that the output control is turned up, that the time-delay relay is operative, and that the fuses are not open.

5.5 TUBE REPLACEMENT. Since the vacuum tubes have a shorter life on the average than the other com-
components used in the instrument, they should be tested if the instrument is still inoperative after the above checks have been made.

The Type 6D4 Gas Triode used as the noise source is aged and selected for uniformity of the noise spectrum and for good amplitude characteristics. If the tube has deteriorated and must be replaced, some selection among different tubes of this type may be necessary to find a satisfactory replacement. Use a tube by the same manufacturer.

5.6 HEATER VOLTAGE OF TYPE 6D4 GAS TUBE. The potentiometer at the rear of the chassis is for setting the heater voltage of the gas tube. Over certain ranges of heater voltage, some gas tubes will "sputter". The meter indication on the 20-kc range will often reveal this sputter. Under normal conditions, the meter reading fluctuates two or three percent. When sputtering occurs; the meter reading may fluctuate 10 percent or more. The sputtering is more easily detected by observation of the noise pattern on an oscilloscope or by ear with a good pair of earphones. The heater voltage should be set so that this sputtering does not occur. Some selection among tubes of this type may be necessary to find a tube that is free from sputtering.

5.7 VOLTAGE MEASUREMENTS. The adjacent tables give test voltages for aid in troubleshooting:

5.8 VOLTOMETER CALIBRATION. To calibrate the voltmeter proceed as follows:

a. Remove all external connections from the Type 1390-B, including the power cable.
b. Zero the mechanical zero of the meter.
c. Set the OUTPUT control fully clockwise.
d. Set the MULTIPLY BY switch to 1.0.
e. Apply 3.0 volts at 1KC from the GR Type 1304-B or equivalent to the Type 1390-B output terminals. The meter must read upscale.
f. Adjust potentiometer R103 (Figure 10) to obtain a reading of 3.3 on the panel voltmeter.
g. Apply 3.0 volts at 500KC from an oscillator with low distortion, using open leads, to the Type 1390-B output terminals and observe that the meter reads between 3.2 and 3.4.
h. Apply 3.0 volts at 5Mc, using open leads, and observe that the meter reads between 3.0 and 3.6.

**NOTES**

Voltages are measured with a 20,000-ohms-per-volt voltmeter and are dc with respect to ground unless otherwise stated.

(A) S3 = 5 Mc
(B) S3 = 500 kc
(C) S3 = 20 kc

* Voltages are measured with a 1000Ω/volt rectifier meter, and are with respect to terminal 11 on transformer T1.
